Theoretical studies on wave turbulence predict that a purely classical system of random waves can exhibit a process of condensation, which originates in the singularity of the Rayleigh-Jeans equilibrium distribution. We report the experimental observation of the transition to condensation of classical optical waves propagating in a multimode fiber, i.e., in a conservative Hamiltonian system without thermal heat bath. In contrast to conventional self-organization processes featured by the nonequilibrium formation of nonlinear coherent structures (solitons, vortices,...), here the self-organization originates in the equilibrium Rayleigh-Jeans statistics of classical waves. The experimental results show that the chemical potential reaches the lowest energy level at the transition to condensation, which leads to the macroscopic population fraction across the transition to condensation are in quantitative agreement with the Rayleigh-Jeans theory. The thermodynamics of classical wave condensation reveals that the heat capacity takes a constant value in the condensed state and tends to vanish above the transition in the normal state. Our experiments provide the first demonstration of a coherent phenomenon of self-organization that is exclusively driven by optical thermalization toward the Rayleigh-Jeans equilibrium.

Several studies based on the wave turbulence theory [1–5] predict that nonlinear waves can exhibit a phenomenon of condensation [2,3,6–17]. This phenomenon of condensation of classical waves differs substantially from the quantum Bose-Einstein condensation (BEC) that has been observed in ultracold atoms and molecules [18], exciton polaritons [19], magnons [20], and photons [21,22]. Although the physics of BEC and classical condensation are different, the underlying mathematical origin is similar because of the common singular behavior (vanishing denominator) of the equilibrium Bose distribution for quantum particles and the equilibrium Rayleigh-Jeans (RJ) distribution for classical waves [3,7]. Here, we report the first observation of the RJ condensation of classical optical waves.

Various forms of condensation processes have been identified in optical cavity systems [19], which are inherently forced-dissipative systems operating far from thermal equilibrium [13,23–30]. On the other hand, equilibrium condensation mediated by the RJ distribution requires a (cavityless) free propagation of the optical beam through a conservative (Hamiltonian) evolution. However, as a consequence of the ultraviolet catastrophe inherent to classical waves, the RJ condensation is not defined for optical free propagation in a bulk medium. In this configuration, only a nonequilibrium transient process of condensation is experimentally accessible [15,17,31]. This problem can be circumvented by considering a waveguide configuration, whose finite number of modes introduces an effective frequency cutoff that regularizes the RJ ultraviolet catastrophe [13,32]. In this framework, a remarkable effect of spatial beam cleaning has been recently reported in multimode optical fibers (MMFs) [33,34]. Although recent works revealed that beam cleaning is characterized by a transfer of power toward the low-order modes of the MMF, the understanding of the underlying mechanism is still debated [32–43]. Yet despite experimental progress, there is still no clear-cut demonstration of the phenomenon of RJ condensation of optical waves.

From a broader perspective, wave condensation can be viewed as a self-organization process characterized by the formation of a large scale coherent structure, a universal behavior found in many fields of physics. As a general rule, the formation of a coherent structure (e.g., solitons, vortices, shock waves,...) requires a strong nonlinear interaction regime [2–14,44–49], as discussed in recent experiments in water tanks [50], vibrating elastic plates [51], BECs [49], or nonlinear optics [12,17,48,52]. More
precisely, wave condensation is usually understood as an inverse turbulence cascade that increases the level of nonlinearity at large scales, up to a breaking point of the weak turbulence theory [3]. Such a nonlinear stage is well known in the focusing regime, where the (Benjamin-Feir) modulational instability leads to the generation of soliton-like structures (“soliton condensation”) [3,12,45–47]. This process is at the root of a variety of phenomena, e.g., optical filamentation [2,3], or soliton-mediated supercontinuum generation in optics [53] and hydrodynamics [54].

In contrast with this large variety of self-organization processes that occur far from thermal equilibrium and require a strong nonlinear interaction [2–10,12–14,44–52], we report in our experiments a different mechanism of spontaneous formation of a coherent structure (condensate) that is driven by the equilibrium RJ statistics in the weakly nonlinear regime. Condensation originates in the RJ distribution for the following reasons: (i) The transition takes place when the chemical potential reaches the fundamental mode eigenvalue, which leads to the macroscopic population of the fundamental mode of the MMF; (ii) the condensate fraction across the transition is in quantitative agreement with the RJ equilibrium theory (without adjustable parameters); (iii) the nonlinearity is perturbative with respect to linear propagation, even in the strongly condensed regime. Furthermore, our thermodynamic approach clarifies the different nature of the classical RJ transition with respect to the quantum BEC transition.

Aside from its fundamental importance, light cooling and condensation find natural applications to achieve an accurate control of the coherence properties of optical beams in high-power multimode fiber sources [55].

**Experimental setup.**—We study the spatial evolution of a speckle beam that propagates through a MMF featured by a parabolic-shaped index of refraction supporting a speckle beam that propagates through a MMF [56]. This provides the linear contribution to the energy (Hamiltonian) \( E = E_{\text{pot}} + E_{\text{kin}} \) projecting on the basis of the fiber modes, the power and energy read \( N = \sum_p n_p, \quad E = \sum_p \beta_p n_p \), where \( n_p \) denotes the power in the mode \( p \) [11]. We have confirmed experimentally that both \( N \) and \( E \) are conserved during propagation in the MMF [56].

**Weakly nonlinear regime.**— The speckle beam that propagates through the MMF exhibits fluctuations that vary over a linear propagation length \( L_{\text{lin}} \) much smaller than the nonlinear length \( L_{\text{nl}} \):

\[
L_{\text{lin}} \sim \beta_0^{-1} \sim 0.2 \, \text{mm} \ll L_{\text{nl}} = 1/(\gamma N) \sim 0.3 \, \text{m},
\]

where \( \gamma \) is the nonlinear coefficient of the MMF. This is equivalent to \( \lambda_{\text{c}} \ll \xi \), where \( \xi = \sqrt{\alpha L_{\text{nl}}} \approx 130 \, \mu\text{m} \) is the healing length, and \( \lambda_{\text{c}} \) the transverse correlation length of the speckle beam, which is typically smaller than the radius of the fundamental mode of the MMF, \( \lambda_{\text{c}} \approx 47 \). This is a consequence of the four-wave interaction underlying the Kerr nonlinearity [13,41]. This is a “closed” (Hamiltonian) system, where the conserved energy \( E \) is the control parameter of the transition to condensation. At equilibrium the modal populations follow the RJ distribution

\[
n_{\text{eq}}^p = T/(\beta_p - \mu),
\]

so that \( N = T \sum_p (\beta_p - \mu)^{-1} \) and \( E = T \sum_p \beta_p/(\beta_p - \mu) \). The solutions to these equations show that the pair \((\mu, T)\) is uniquely determined by the conserved quantities \((N, E)\) [7,13,42] (\( T \) is in units of \( \text{W} \cdot \text{m}^{-1} \) and it is not defined by a thermostat). At variance with previous experiments of spatial beam cleaning [33–36,40,43], here we study the transition to condensation by decreasing the energy \( E \) (“temperature”) while keeping constant the power \( N \) (“number of particles”)—\( E \) being varied owing to the diffuser before injection in the MMF [56].

We stress that RJ thermalization does not imply condensation: Here condensation occurs because the four-wave interaction is a 2 ↔ 2 resonance with two conserved quantities \((N, E)\). Systems like capillary waves, acoustic
waves, Rossby planetary waves, or vibrating elastic plates do not conserve the “wave-action” $N$, so that $\mu = 0$ and condensation cannot take place: The fundamental mode cannot be macroscopically populated, i.e., $n_{\text{eq}}^0 \approx n_p^\text{eq}$ (for small $p$) whatever the energy.

Note that the stationary distribution describing light condensation in forced-dissipative lasers [27–30] resembles Eq. (2), provided one substitutes the $\beta_p$ and the $\mu$ with the cavity losses and the gain, while $T$ is fixed by a thermostat in Refs. [27–30]. Accordingly, the stationary distribution and its underlying mechanism of relaxation in Refs. [27–30] are fundamentally different from the RJ thermalization discussed here.

Considering the parabolic potential $V(r)$ and the corresponding invariance of the Hermite-Gauss modes ($w_p$) under Fourier transform, we have expressed the mean NF and FF intensities in equivalent forms. Splitting the condensate and the incoherent contributions $N = n_{\text{eq}}^0 + \sum_{p \neq 0} n_p^\text{eq}$, we obtain [56]

$$I_{\text{NF}}^\text{cond}(r) = n_{\text{eq}}^0 r_0^2 w_0^2(r/r_0), \quad I_{\text{FF}}^\text{cond}(k) = n_{\text{eq}}^0 r_0^2 w_0^2(r_0k),$$

(3)

for the fundamental mode, and

$$I_{\text{NF}}^\text{inc}(r) = T \sum_{p \neq 0} r_0^2 w_p^2(r/r_0)/(\beta_p - \mu),$$

(4)

$$I_{\text{FF}}^\text{inc}(k) = T \sum_{p \neq 0} r_0^2 w_p^2(r_0k)/(\beta_p - \mu),$$

(5)

for the incoherent contribution from the other modes. The total intensity is $I_{\text{NF}}(r) = I_{\text{NF}}^\text{cond}(r) + I_{\text{NF}}^\text{inc}(r)$ (idem for the FF), with $N = \int I_{\text{NF}}(r) \, dr = \int I_{\text{FF}}(k) \, dk$, and $r = |r|$, $k = |k|$.

We performed averages from a total number of $2 \times 1000$ measurements of the NF and FF intensity distributions recorded for a fixed power $N = 7$ kW. We report in Figs. 1(a)–1(b) the NF and FF intensities for the same energy $E$ (corresponding to $n_{\text{eq}}^0/N \approx 0.4$) that have been averaged over the realizations (blue lines). The experimental results are compared to the theoretical RJ intensity distributions (dashed red lines). The quantitative agreement in Figs. 1(a)–1(b) is obtained without any adjustable parameter: The experimentally measured energies $(E, N)$ determine a unique pair $(\mu, T)$, which in turn determines the intensity distributions $I_{\text{NF}}^\text{inc}(r)$ and $I_{\text{FF}}^\text{inc}(r)$ from Eqs. (3)–(5). As a result of the averaging procedure, the NF and FF representations are equivalent to each other [Eqs. (3)–(5)], as evidenced experimentally in Figs. 1(a)–1(b).

We compare the “output” intensity distributions recorded at 12 m with the “input” intensities recorded after 20 cm of propagation in the MMF (“initial conditions”). Figures 1(c)–1(d) report the NF and FF individual realizations of the input and output beams corresponding to the averaged intensities of Figs. 1(a)–1(b): The input-to-output reduction of fluctuations enlightens the role of “statistical attractor” of the RJ distribution.

To characterize the RJ attraction process, we introduce a distance that measures the degree of similarity between the radial intensity distribution of a beam recorded experimentally and the theoretical RJ intensity: $D = \sum_i |I_{\text{NF,exp}}(r_i) - I_{\text{NF}}^\text{inc}(r_i)|^2/\sum_i I_{\text{NF}}^\text{inc}(r_i)^2$, where $r = |r|$ and $r_i$ the corresponding spatial grid. The strong reduction of $D$ from the input to the output beams confirms the thermalization to the RJ equilibrium; see Fig. 1(e) (the limited reduction of $D$ for $E > E_{\text{crit}}$ is due to the polar-angle averaging procedure).

Rayleigh-Jeans condensation.—At variance with homogeneous condensation in a bulk medium [$V(r) = 0$] [3,7], the presence of the parabolic potential reestablishes condensation in the “thermodynamic limit” in two dimensions. There exists a (nonvanishing) critical energy $E_{\text{crit}}^* = NV_0/2$. 

![Image](image.png)
such that $\mu = \beta_0$ [11,56]. At this critical point the denominator of the RJ distribution vanishes exactly [7] and the singularity is regularized by the macroscopic population of the fundamental mode [11,56]:

$$n_0^{\text{eq}} / N = 1 - (E - E_0)/(E^{\ast}_{\text{crit}} - E_0).$$

(6)

Then, $n_0^{\text{eq}}$ vanishes at $E^{\ast}_{\text{crit}}$ and $n_0^{\text{eq}} / N \rightarrow 1$ as $E$ reaches the minimum $E_0 = N\beta_0$. This mechanism of RJ condensation is formally analogous to the quantum Bose-Einstein transition, which originates in the singularity of the Bose distribution when the chemical potential reaches the ground state energy [7,18].

Because of finite size effects, the experiment does not occur in the strict thermodynamic limit. The theory accounting for finite size effects gives $E^{\ast}_{\text{crit}} = E_0[1 + (M - 1)/q]$, where $q = \sum_{p \neq 0}(p_x + p_y)^{-1}$ [11,13,56]. Considering the experimental parameters we obtain $E^{\ast}_{\text{crit}} / E^{\ast}_{\text{crit}} \approx 0.95$ [blue cross in Fig. 2(b)], so that our experiment is “close” to the thermodynamic limit.

In order to compare the theory with the experiments, we need to extract $n_0^{\text{eq}}$ and $\mu$ from the experimental data. This requires a fitting procedure: Using the experimental intensities averaged over the realizations, we have retrieved $(n_0^{\text{eq}}, \mu)$ from the RJ intensity distributions [Eqs. (3)–(5)] by a least squares method [56]. For this purpose, the temperature $T$ in Eqs. (4)–(5) has been expressed in terms of $(n_0^{\text{eq}}, \mu)$ by using $N = n_0^{\text{eq}} + T\sum_{p \neq 0}(\beta_p - \mu)^{-1}$. In this way $(n_0^{\text{eq}}, \mu)$ can be extracted independently from either the NF or FF intensity distributions.

We report in Fig. 2(a) the chemical potential $\mu$ vs $E$: By decreasing $E$, $\mu$ increases and condensation occurs when $\mu = \beta_0$ for $E = E^{\ast}_{\text{crit}}$. Below the transition ($E \leq E^{\ast}_{\text{crit}}$) the fundamental mode gets macroscopically populated, $n_0^{\text{eq}} \gg n_0^{\text{eq}}$, see Fig. 2(b). The triangles report the experimental data retrieved from the least square method for the NF and FF intensity distributions. The red line reports the RJ theory accounting for finite size effects for the MMF used in the experiment; see Refs. [11,56]. The experimental results in Fig. 2 are in quantitative agreement with the RJ theory without adjustable parameters, i.e., $\beta_0$ and $M$ are fixed by the MMF of the experiment [56]. Furthermore, the experimental results are close to the thermodynamic limit given by Eq. (6), see Fig. 2(b). As usual, finite size effects make the transition to condensation “smoother” [red line in Fig. 2(b)].

**Thermodynamics of classical condensation.**—We start from the *equilibrium* entropy $S^\text{eq} = \sum_p \log(n_p^{\text{eq}}) - M \log N$ that can be written $S^\text{eq}(E) = -\sum_p \log(\beta_p - \mu(E)) - M \log(\sum_p(\beta_p - \mu(E))^{-1})$. Figure 3(a) reports $S^\text{eq}$ vs $E$ by using the experimental data $\mu(E)$ in Fig. 2(a). The heat capacity $C_V = (\partial E/\partial T)_{N,M}$ is an important quantity characterizing the transition to condensation [18]. In our experiment the transition is studied by varying $E$ while holding $N$ and $M$ constant ($M$ playing a role analogous to the system volume [32]). Using the energy-temperature relation $E = T = (\partial E/\partial S^\text{eq})_{N,M}$ in Fig. 3(b), we obtain [56]

$$C_V(E) = M - \frac{\{\sum_p(\beta_p - \mu(E))^{-1}\}^2}{\sum_p(\beta_p - \mu(E))^{-1}}.$$  

(7)

Below the transition ($E < E^{\ast}_{\text{crit}}$) we have $\mu \rightarrow \beta_0$. Then writing the energy in the form $E = TM + \beta_0 N$ gives $C_V = M$, as expected from the theorem of energy equipartition, see Figs. 3(c)–3(d).

![FIG. 2. Rayleigh-Jeans condensation. (a) Chemical potential vs energy: For $E \leq E^{\ast}_{\text{crit}}$, $\mu \rightarrow \beta_0$, which leads to the macroscopic population of the fundamental mode, see $n_0^{\text{eq}} / N$ vs $E/E^{\ast}_{\text{crit}}$ (b). The blue (yellow) triangles report the experimental results from the NF (FF) intensity distributions (averaged over the realizations). The red lines report the RJ theory without using adjustable parameters. The dashed black line in (b) refers to the thermodynamic limit [Eq. (6)] and the blue cross denotes $E^{\ast}_{\text{crit}} / E^{\ast}_{\text{crit}} \approx 0.95$: The experiment is “close” to the thermodynamic limit.](image)

![FIG. 3. Thermodynamics of classical condensation. (a) Entropy $S^\text{eq}$ vs $E/E^{\ast}_{\text{crit}}$; (b) $E/E^{\ast}_{\text{crit}}$ vs $T/T^{\ast}_{\text{crit}}$. Heat capacity $C_V / M$ vs $E/E^{\ast}_{\text{crit}}$ (c), and vs $T/T^{\ast}_{\text{crit}}$ (d). The blue (yellow) triangles report the experimental results from the NF (FF) intensity distributions (averaged over the realizations). The solid red lines report the RJ theory without adjustable parameters ($M = 120$ modes). For $E < E^{\ast}_{\text{crit}}$ (or $T < T^{\ast}_{\text{crit}}$) the system exhibits energy equipartition among the modes and $C_V / M \rightarrow 1$, whereas for $E > E^{\ast}_{\text{crit}}$ (or $T > T^{\ast}_{\text{crit}}$) the equipartition of power among the modes entails $C_V \rightarrow 0$ (dashed-black lines are for $M = 500$ 500).](image)
Far above the BEC transition a quantum gas behaves as a classical gas featured by a constant heat capacity $C_V(T) = \text{const}$ [18]. At variance with a classical gas, we observe in our classical wave system that $C_V \to 0$ for $E > E_{\text{crit}}$ (or $T > T_{\text{crit}} = N\beta_0/\rho$), see Figs. 3(c)–3(d). Actually, the equilibrium properties of waves are of a different nature than those of a gas: Above the transition the equilibrium state no longer exhibits energy equipartition, but instead an equipartition of the power among the modes, viz $n_p^0 \sim T/(\mu \beta_p)$. This is the most disordered equilibrium state with $S_{\text{max}} = -M \log M$ for $E = 3/2 NV_0$ and $1/T = (\partial S/\partial E)_{N,M} \to 0$. This means that the equilibrium is not constrained by the conservation of the energy $E$ (the Lagrange multiplier $1/T$ is zero), but solely by the conservation of $N$, which merely explains the modal power equipartition [60]. Accordingly, a variation of $T$ does not affect $E$, which entails $C_V \to 0$. Approaching the thermodynamic limit, $C_V$ exhibits a cusp featured by an infinite derivative at $E = E_{\text{crit}}$ (or $T = T_{\text{crit}}$); see Figs. 3(c)–3(d).

Conclusion.—We have reported the first observation of the equilibrium condensation of classical optical waves in quantitative agreement with the RJ theory. Far above the transition, the field exhibits an equipartition of power among the modes and a vanishing heat capacity $[C_V(T) \to 0]$. Below the transition ($E < E_{\text{crit}}$), the fundamental mode is macroscopically populated and the constant heat capacity reflects an energy equipartition among the uncondensed modes.

Our experiments in MMFs pave the way for a thermodynamic control of light coherence [32,61]. For instance, a thermalized speckle beam in the normal state can be adiabatically cooled to the condensed state owing to a potential sink in a manufactured MMF, in analogy with the adiabatic formation of quantum BECs [18].
