(Received 11 March 2021; accepted 30 June 2021; published 15 July 2021)

We study the out-of-equilibrium dynamics of a two-dimensional paraxial fluid of light using a near-resonant laser propagating through a hot atomic vapor. We observe a double shock-collapse instability: a shock (gradient catastrophe) for the velocity as well as an annular (ring-shaped) collapse singularity for the density. We find experimental evidence that this instability results from the combined effect of the nonlocal photon-photon interaction and the linear photon losses. The theoretical analysis based on the method of characteristics reveals the main result that dissipation (photon losses) is responsible for an unexpected enhancement of the collapse instability. Detailed analytical modeling makes it possible to evaluate the nonlocality range of the interaction. The nonlocality is controlled by adjusting the atomic vapor temperature and is seen to increase dramatically when the atomic density becomes much larger than one atom per cubic wavelength. Interestingly, such a large range of the nonlocal photon-photon interaction is observed in an atomic vapor here, but its microscopic origin is currently unknown.

I. INTRODUCTION

It has long been realized that light propagating in a nonlinear medium under the paraxial approximation can be interpreted in the context of quantum fluid dynamics [1–3]. Such phenomena in nonlinear Kerr-like media that we recently call fluids of light have been investigated in photorefractive crystals [4,5], thermo-optic liquids [6,7], and hot atomic vapors [8–11]. In this paper, we use a hot atomic vapor to study the impact of dissipation and the nonlocal character of the interactions in the shock-wave dynamics [12]. The theory of dispersive shock waves has been developed for a long time [13] after pioneering investigations in the fields of tidal waves [14–16] and collisionless plasma [17–19]. It has been only recently that dispersive shock waves have emerged as a general signature of singular fluid-type behavior [20–24] in areas as different as Bose-Einstein condensates [25–27], shallow water [28], oceanography [29], plasma [30], viscous fluid conduits [31], and several optical systems, e.g., photorefractive crystals [32–34], passive cavities [35], and optical fibers [36–42]. An important ramification is the study of shock waves in the presence of a spatial nonlocal nonlinearity, a feature studied experimentally in liquids with strong thermo-optic effects [43–51]. A nonlocal interaction means that the response of the nonlinearity at a particular point is not only determined solely by the wave intensity at that point, but also depends on the wave intensity in its vicinity. In this context, shock-wave formation from a random speckled beam revealed that a highly nonlocal nonlinearity leads to a double shock-collapse singularity [50,52]: Whereas the gradient phase of the field (velocity) develops a shock, the intensity (density) develops a collapse instability on the edge of the ring-shaped beam, i.e., annular collapse. On the other hand, we note that numerical simulations have shown the effect of nonlocal stabilization of nonlinear beams in a self-focusing atomic vapor [53]. In these works, the dissipation has been considered as a negligible perturbative effect.

Here, we report the observation of the double shock-collapse instability in a fluid of light in an atomic vapor. Our main result is to reveal a previously unrecognized and counterintuitive impact of the dissipation: The linear absorption of the optical field (i.e., the fluid of light) is shown to be responsible for an enhancement of the collapse instability. This unexpected result is enlightened by the theoretical analysis based on the method of characteristics for solving the hydrodynamic equations. Our paper then also contributes to the development of the concept of “gain through losses” in nonlinear optics where specific frequency-distributed losses can be imaged into spectral gain [54,55].

An important aspect of our experimental work is to unveil a strong nonlocal regime for fluids of light propagating in hot atomic vapors. Contrary to previous studies on atomic vapors [56–59] where interactions were seen to be local, we tuned the atomic density up to 20 atoms per cubic wavelength (by changing the temperature of the gas) which leads to an observable signature of nonlocality. By comparing our experimental data to numerical simulations we give an estimate of the range of the nonlocal interactions in our system. We propose a possible origin for such an unexpected large value of nonlocality reported in this paper.
Our fluid of light is a continuous-wave laser beam which propagates in a nonlinear Kerr-like medium along the $z$ axis. Under the paraxial approximation, the dynamics of the slowly varying amplitude $\psi$ of the laser electric field is commonly described by the nonlinear Schrödinger (NLS) equation \cite{1}. We consider the standard form of the nonlinear NLS equation,

$$i \frac{\partial \psi}{\partial t} = -\frac{\alpha}{2} \nabla^2 \psi - i \frac{\eta}{2} \psi + \gamma \psi \int d^3 r |\psi(r')|^2 \delta(r - r'), z,$$

(1)

where $\nabla$ is defined on the transverse plane $r = (x, y)$ and the propagation axis $z$ plays the role of an effective time. $\alpha = 1/k_0$ is the dispersion (diffraction) parameter, where $k_0$ denotes the wave number of the laser and plays the role of an effective mass. $\eta$ quantifies the strength of the linear absorption in the medium. The interaction term includes an isotropic nonlinear response function $U(r) = U(|r|)$ with the parameter $\gamma = k_0 n_2$ that quantifies the strength of the interaction with $n_2$ being the Kerr nonlinear index. We consider the repulsive photon-photon interactions (defocusing) regime $\gamma > 0$. We consider the examples of an exponential-shaped normalized response function $U(r) = (2\pi \sigma^2)^{-1} \exp(-|r|/\sigma)$, but similar results are obtained with a Gaussian-shaped response $U(r) = (2\pi \sigma^2)^{-1} \exp(-|r|^2/(2\sigma^2))$. Note that, in addition to atomic vapors \cite{53}, a nonlinear nonlinearity is found in several systems, e.g., dipolar Bose-Einstein condensates \cite{60}, nematic liquid crystals \cite{61}, glasses \cite{62}, liquids \cite{51}, or plasmas \cite{63}.

II. EXPERIMENTAL INVESTIGATION

We use an $L = 7$-cm-long cell filled with a gaseous natural isotopic mixture of $^{85}$Rb and $^{87}$Rb as nonlinear medium. The fluid is created with a linearly polarized Ti:sapphire laser whose wavelength $\lambda$ is tuned near the $D_2$ resonance of $^{87}$Rb. The laser detuning is adjusted from $-14$ to $-2$ GHz with respect to the $F = 2 \rightarrow F'$ transition of $^{87}$Rb. In this range, the detuning is large compared to the Doppler broadening ($\sim 250$ MHz) such that the Lorentzian shape of the line dominates. The atomic vapor density is controlled by adjusting and stimulating the temperature of the cell from $100 \degree C$ to $160 \degree C$, which corresponds to a range of one $^{87}$Rb atom per $\lambda^3$ to 20 atoms per $\lambda^3$, respectively. With these two parameters (laser detuning and temperature), we can adjust the nonlinear Kerr index $n_2$ and, thus, the effective photon-photon interaction $\gamma$. To calibrate the value of $n_2$, we measure the far field intensity of a collimated Gaussian beam with initial waist of $0.7$ mm and peak intensity $I = 6.5 \times 10^5$ W m$^{-2}$. Due to self-phase modulation, this configuration generates concentric rings and provides a direct measurement of the nonlinear phase $\phi_{NL} = k_0 n_2 I L$ accumulated by the beam along its propagation. In this paper, we measure values of $n_2$ from $1 \times 10^{-11}$ to $3.8 \times 10^{-10}$ m$^2$ W$^{-1}$ \cite{64}.

The experimental setup is depicted in Fig. 1(a). We set the initial dimension of the fluid of light by demagnifying the beam down to a waist of $w = 0.32$ mm. The waist is located at $z = 0$, and the Rayleigh length of the initial beam $z_R = \pi w^2/\lambda \simeq 40$ cm exceeds the length of the cell. The total power can be adjusted from 0 to 1 W, leading to a peak intensity between 0 and $I = 6.2 \times 10^6$ W m$^{-2}$. In Fig. 1(b), we present a typical image of the cell output intensity compared to the input beam size. A clear difference between the initial and the final dimensions of the fluid is visible due to the repulsive photon-photon interaction. Figure 1(c) shows a typical radial cut of the intensity profile that we use to study the dynamics of the fluid.

The experimental protocol consists of fixing the laser transmission by adjusting the laser detuning $\Delta$ after the cell has been heated to a given temperature $T$. Then we explore the dynamics of the fluid of light by varying the beam power. The radial intensity profiles are shown in Fig. 2. Here we show data for a cell temperature of $150 \degree C$ and a transmission of 40%. From each dataset (temperature and transmission) we can identify the development of a shock wave. For early effective times, we observe a clear self-steepening of the shock front as expected for a conventional shock wave \cite{41}. Note that, in our experiment the shock wave builds even in the absence of a background fluid to sustain it \cite{37}. This is confirmed for late times where the wave breaking is regularized by the dispersion effects and the formation of the characteristic rapidly oscillating density front. Although the appearance of a shock is theoretically associated with a gradient catastrophe of the velocity since our experimental observable is the density we define the critical power $P_{\text{Shock}}$ as the beam power beyond which a dispersive oscillating structure emerges at the front of the density profile. In Fig. 2 we can see that $P_{\text{Shock}} = 0.3$ W, and we can also note that, as expected, the spatial period of the oscillating front is typically given by the healing length $\Lambda$, which is the spatial length scale for which linear and nonlinear effects are on the same order. In the case of the NLS Eq. (1) we have $\Lambda = \sqrt{2k_0 \gamma T_f}$ where $T_f$ is the local value of the intensity $I_f$ at the shock front. We obtain $\Lambda \simeq 50 \mu m$ in the case of Fig. 2.
At the critical power \( P_{\text{shock}} \), the beam exhibits a pronounced peak intensity on the ring-shaped shock front. This observation is similar to that reported in liquids with strong thermo-optic effects \([47,50]\). It is also apparently similar to the collective incoherent shock dynamics of speckle beams where the annular instability on the shock front was recognized as a collapse singularity \([52]\). Such an instability is termed annular collapse because it does not occur as usual at a single spatial point but on the circular edge of the ring-shaped beam. The main result of our experiments is that such an annular peak intensity is enhanced: (i) at high temperature (high nonlocality) and (ii) at low transmission (high dissipation), which regularizes the shock with a spatial period given by the healing length \( \Lambda \). The inset: Normalized maximum intensity of the collapse peak as a function of the beam power. It hints at a faster-than-linear growth (respectively, slower) below \( P_{\text{shock}} \) (respectively, beyond) in agreement with our theoretical analysis.

**FIG. 2.** Output normalized radial intensity profiles for different input powers. The intensity profiles are normalized with respect to the maximum of the intensity profile at 660 mW. The cell is heated to \( 150^\circ \text{C} \), the laser detuning is \( \Delta = -5.5 \text{ GHz} \), and the transmission is \( T = 40\% \). By looking at the different profiles we can identify the critical power \( P_{\text{shock}} = 300 \text{ mW} \) beyond which the front profile is characterized by the formation of the rapidly oscillating density, which regularizes the shock with a spatial period given by the healing length \( \Lambda \). The intensity is renormalized to improve the comparison of the collapse instability.

**III. THEORY, SIMULATIONS, AND DISCUSSIONS**

In this section, we explain why the nonlocal nonlinearity combined with dissipation has a dramatic impact on the fluid dynamics. Using the method of characteristics and numerical simulations, we demonstrate that the presence of dissipation changes the nature of the singularity and leads to the formation of a double shock collapse singularity.

Starting from the NLS Eq. (1), we make the change in variable \( \Psi(r, z) = \psi(r, z) \exp(i\eta z/2) \) to get

\[
i \partial_t \Psi = -\frac{\alpha}{2} \nabla^2 \Psi + \gamma e^{-\eta z} \Psi \int U(r-r')|\Psi|^2(r', z)dr'.
\]  

Following the Madelung transformation, the wave amplitude factors as \( \Psi(r, z) = \sqrt{\rho(r, z)} \exp(i\phi(r, z)) \), and the NLSE (2) takes the form

\[
\partial_t \rho + \alpha \nabla \cdot (\rho \nabla \phi) = 0,
\]

\[
\partial_t \phi + \frac{\alpha}{2} (\nabla \phi)^2 + e^{-\eta z} V = \frac{\alpha}{2\sqrt{\rho}} \nabla^2 \sqrt{\rho},
\]

with the potential,

\[
V(r, z) = \gamma \int U(r-r')\rho(r', z)dr'.
\]

Defining an analog of the velocity \( u = \nabla \phi \), we get the following dispersive hydrodynamiclike equations:

\[
\partial_t \rho + \alpha \nabla \cdot (\rho u) = 0,
\]

\[
\partial_t u + \alpha (\nabla u)u + e^{-\eta z} \nabla V = \frac{\alpha}{2} \nabla \left( \frac{1}{\sqrt{\rho}} \nabla^2 \sqrt{\rho} \right).
\]

In the experiment, the initial Gaussian beam is radially symmetric with \( u(r, z = 0) = 0 \). In cylindrical coordinates, the momentum is radially outgoing \( u = u(r, z)|\rho/r| \) with \( r = |r| \), whereas \( \rho = \rho(r, z) \) is independent of the polar angle \( \theta \). Indeed, such a radial symmetry is verified by the initial condition and the dispersive hydrodynamic equations preserve this property during the propagation in \( z \). The hydrodynamic equations (6) and (7) can, thus, be reduced to the effective...
one-dimensional-radial system,
\[
\partial_z \dot{\rho} + \alpha \partial_z (\dot{\rho} u) = 0,  \quad (8)
\]
\[
\partial_z u + au \partial_z u + e^{-\nu} \partial_z V = \frac{\alpha}{2} \partial_z \left( \frac{1}{\sqrt{r^2 + \rho^2}} \partial_z \sqrt{\rho} \right), \quad (9)
\]
where \( \dot{\rho}(r, z) = r \rho(r, z) \) and the potential is given by
\[
V(r, z) = \gamma \int_0^\infty U(r, r') \rho(r', z) r' \, dr', \quad (10)
\]
with \( U(r, r') = \int_0^{2\pi} U(\sqrt{r^2 + r'^2 - 2rr' \cos \theta}) \, d\theta \).

Considering the strongly nonlinear regime inherent to the development of shock waves, the impact of dispersion effects in the right-hand side of (9) can be neglected before the occurrence of the singularity. In this nondissipative regime, Eqs. (8) and (9) take the form of hydrodynamiclike equations accounting for the nonlocality and the dissipation,
\[
\partial_z \dot{\rho} + \alpha \partial_z (\dot{\rho} u) = 0, \quad (11)
\]
\[
\partial_z u + au \partial_z u + e^{-\nu} \partial_z V = 0. \quad (12)
\]

Before pursuing, it proves convenient to briefly recall the usual local limit without dissipation. In this regime, Eq. (12) reduces to \( \partial_z u + au \partial_z u + \gamma \partial_z \rho = 0 \). Starting from \( u(r, z) = 0 \), the velocity \( u(r, z) \) is first driven by the last term in (12). Then the dynamics is dominated by the Hopf (or inviscid Burgers) second term in (12), which leads to the gradient catastrophe of the velocity \( u(r, z) \). When combined to (11), the system then develops a radial symmetric annular shock that is characterized by a divergence of \( \partial_z u \) and \( \partial_z \rho \), whereas \( \rho \) remains finite and does not blow up [12]. We recall that the system does not develop, strictly speaking, a singularity at finite propagation distance because the neglected dispersive terms (right-hand side in (9)) become important nearby the shock distance (the propagation distance that corresponds to the onset of the dispersive, oscillating structure at the front of the density profile). The dispersive effects regularize the singularity [41], i.e., the system does not develop a shock in the Rankine-Hugoniot sense [12].

The scenario discussed here above also holds in the weakly nonlocal regime \( \sigma \ll \Lambda \). On the other hand, in the regime \( \sigma > \Lambda \), the nonlocality changes the nature of the singularity. The main observation is that, at variance with \( \partial_z V \) in (12) exhibits a regular behavior around the shock position. This regularization of \( \partial_z \rho \) has a dramatic effect: In the absence of nonlocality (\( \sigma = 0 \)), the term \( \gamma \partial_z \rho \) was preventing from the growth of the amplitude of \( \rho \) but without such a term, the amplitude of \( \rho \) does grow.

This behavior is revealed by applying the method of characteristics [66] to the hyperbolic system Eqs. (11) and (12). We define \( u(z) = u(R(z), z) \), \( \tau(z) = \partial_z u(R(z), z) \), \( \xi(z) = \partial_z u(R(z), z) \), \( \hat{\rho}(z) = \hat{\rho}(R(z), z) \) by following a specific characteristic \( R(z) \) with \( R(0) = r_0 \). These functions can be shown to satisfy the following system of ordinary differential equations:
\[
\frac{dR}{dz} = \alpha w(z), \quad (13)
\]
\[
\frac{dw}{dz} = \tau(z) + \alpha u(z) \xi(z), \quad (14)
\]
\[
\frac{d\tau}{dz} = -\partial_z^2 [e^{-\nu} V(R(z), z)] - \alpha \xi(z) \tau(z), \quad (15)
\]
\[
\frac{d\xi}{dz} = -\partial_z^2 [e^{-\nu} V(R(z), z)] - \alpha \xi^2(z), \quad (16)
\]
\[
\frac{d\hat{\rho}}{dz} = -\alpha \xi(z) \hat{\rho}(z). \quad (17)
\]

From the formal point of view, these equations are analogous to those derived in the framework of the long-range Vlasov formalism in the strong turbulence regime [52,67,68] or to describe the emergence of phase coherence from a random speckled beam [69]. Note that the impact of dissipation has not been discussed in these previous works.

The development of the double shock collapse singularity is driven by the velocity gradient in Eq. (16). In the first term of (16), the amplitude of \( \partial_z^2 V \) can be bounded by the maximal amplitude of \( \hat{\rho} \) divided by \( \sigma^2 \). On the other hand, the second term in (16) describes a divergence of the form \( |\xi| \sim 1/(z_\infty - z) \) close to the shock point \( z_\infty \). Thus, there exists some propagation length beyond which the term \( -\alpha \xi^2 \) dominates \( \partial_z^2 V(r, z) \), and \( \xi(z) \) blows up in finite effective time \( z \). Remarkably, in the shock point \( z = z_\infty \), we obtain the singular behaviors of \( \xi(z) \) and \( \hat{\rho}(z) \) just before \( z = z_\infty \).

\[
\partial_z u(R(z), z) \sim -1/[\alpha(z_\infty - z)], \quad (18)
\]
\[
\hat{\rho}(R(z), z) \sim \hat{\rho}(r_0, z_\infty)(z_\infty - z_0)/(z_\infty - z). \quad (19)
\]

Note the quantitative agreement obtained in Figs. 4(a)–4(e) between the simulations of the NLS Eq. (1), the hydrodynamic Eqs. (8) and (9), and the characteristic Eqs. (13)–(17), without using adjustable parameters. Note that we considered a Gaussian-shaped response function. We remark that the singularity is not regularized by the dissipation (as for conventional diffusive shocks [12]), but by the dispersion effects neglected in Eqs. (8) and (9), which leads to the formation of the characteristic rapidly oscillating density front observed in the experiments, see Fig. 2.

This analysis unveils the unexpected role of the dissipation. By quenching the first term in Eq. (16), dissipation \( \eta \) favors the growth of \( |\xi| \) described by the second term, which, in turn, favors the growth of \( \hat{\rho}(z) \) before the singularity. This effect is illustrated in Fig. 5(a) where the dissipation is seen to strengthen the development of the collapse singularity at fixed nonlocality. Our experimental data, shown in Fig. 3, confirm this prediction since the amplitude of the collapse instability is enhanced by slightly decreasing the transmission from 40% to 20%. Similarly, our results show that the nonlocality favors the development of the shock-collapse singularity by quenching the bounds of \( \partial_z^2 V(r, z) \) in (16). This is illustrated in Fig. 5(b) that reports the density profiles nearby the shock point for different amounts of nonlocality.
We find a nonlocality of $160^\circ$ required to describe quantitatively our experimental results. Since, in hot atomic vapors, nonlocality is usually attributed to the ballistic transport of fast-moving excited atoms, which results in a nonlocal length scale on the order of $σ \approx 7.5 \, \mu m$ for $160^\circ$ [53,70,71]. The larger nonlocal length scale needed to explain our observation requires to go beyond the simple two-level model used in [53] and includes more complex atom-light interaction, including, for instance, possible optical pumping [72] with long-range memory, the diffusive motion of atoms [71], collisional broadening [73], and other collective optical response mechanisms.

**IV. CONCLUSION**

To summarize, we have reported the observation of a shock-collapse instability for the evolution of velocity and the intensity of an optical field propagating in an atomic vapor. We have shown experimentally and theoretically that the linear dissipation combined to the nonlocal nonlinearity is responsible for a significant enhancement of the collapse instability. Furthermore, the theoretical analysis can be applied to a purely local nonlinear interaction, which remarkably

Using this model, we estimate the amount of nonlocality required to describe quantitatively our experimental results. We find a nonlocality of $σ \approx 70 \, \mu m$ for a temperature of $160^\circ$ C. Such a large nonlocality coefficient is unexpected since, in hot atomic vapors, nonlocality is usually attributed to the ballistic transport of fast-moving excited atoms, which results in a nonlocal length scale on the order of $σ \approx 7.5 \, \mu m$ for $160^\circ$ C [53,70,71]. The larger nonlocal length scale needed to explain our observation requires to go beyond the simple two-level model used in [53] and includes more complex

**FIG. 5.** (a) Density profile $ρ(r)$ for different values of the transmissions $T$ (i.e., different $η$’s) but for the same effective nonlinear propagation length $z_{NL} = \frac{1 - \exp(-ηz)}{η} = 120\ell_{NL}$ ($σ = 70 \, \mu m$), (b) Density profile $ρ(r)$ for different values of nonlocality $σ$ (in microns) nearby the shock point $z_{sh}$ ($T = 60\%$). The $r$ axis is in units of $δ$, and the density $ρ$ is in units of $f$. Note that, to improve the visualization, all plots in (a) have been normalized to the power for $T = 100\%$.

**FIG. 6.** Transmission of the laser beam through the cell as a function of the detuning of the laser (same reference as the one of the main text). From the transmission profile a fit to the data allows us to deduce the temperature of the gas. For this particular curve, we find $T = 110^\circ$ C.
reveals that the shock formation (density gradient collapse) is associated with a density collapse only if there is dissipation. Our experimental platform enables the study of the crossover from a local nonlinear interaction to a nonlocal one by tuning the temperature of the vapor cell. We observed a nonlocal interaction which is an order of magnitude larger than previously reported for ballistic transport. These results open the way to tunable nonlocal physics with fluids of light and require multilevel atoms modelization to identify the microscopic mechanisms responsible for this effect.

APPENDIX: EXTRACTION OF THE TEMPERATURE OF THE GAS

To extract the temperature of the atomic gas, we record the transmission profile of a weak laser beam through the cell as a function of the laser detuning. By fitting this data using a numerical simulation that takes into account the atomic lines of the two isotopes, the Doppler broadening, and the rubidium vapor pressure as a function of the temperature [74,75], we can infer the temperature of the gas as shown in Fig. 6.

[65] See supplemental Material at https://link.aps.org/supplemental/10.1103/PhysRevA.104.013515 for a Movie that provides a visualization of the complete dynamics of the numerical simulation reported in Fig. 4.
